1. Purpose and Background

Purpose

The purpose of this review is to provide an update of the 2005 Canadian Task Force recommendations on screening for type 2 diabetes to prevent vascular complications (Feig, Palda, & Lipscombe, with the Canadian Task Force on Preventive Health Care (CTFPHC), 2005). The goal of this update is to determine the effectiveness of screening for type 2 diabetes, and for impaired fasting glucose (IFG) and/or impaired glucose tolerance (IGT), in adults over the age of 18 years for the prevention of diabetes progression and vascular complications.

The US Preventive Service Task Force (USPSTF) updated their 2003 guidelines in 2008 (Norris, Kansagara, Bougatsos & Fu, 2008). The absence of recent Canadian recommendations was the basis for selecting this topic for an update by the revitalized Canadian Task Force in 2010.

Condition Background

Definition

Diabetes mellitus represents a cluster of chronic metabolic diseases characterized by hyperglycemia as a result of defective insulin secretion, defective insulin action or both. Persistent hyperglycemia is associated with consequences resulting in injury or failure of the micro or macrovasculature, such as the nerves, kidneys, eyes, blood vessels and heart (Gerstein & Haynes, 2001).
Previously known as adult-onset diabetes or non-insulin dependent diabetes, the impetus for changing the name reflects the detection of type 2 diabetes in children and adolescents and the proliferate use of insulin in its management. Type 2 diabetes comprises the majority of diabetes cases nationally and globally, and is often asymptomatic in early stages, remaining undiagnosed for long periods of time (Cowie, Rust, Byrd-Holt, 2006).

Type 2 diabetes is a heterogeneous metabolic disorder with both genetic and environmental determinants. Predominant insulin resistance with relative insulin deficiency and/or predominant secretory defects with insulin resistance are characteristics of type 2 diabetes (Ur, 2008). Optimal management of type 2 diabetes requires early and ongoing lifestyle modification; including physical activity and nutrition, self-management training and pharmacotherapy (Vermeire, Wens, VanRoyen, Biot, Hearnshaw, Lindenmeyer, et al., 2005; Ismail, Winkley & Rabe-Hesketh, 2004; Goudswaard, Stolk & Zuithoff, et al., 2004).

Prevalence and burden of disease

In Canada in 2006-2007, there were an estimated 199,471 new cases of diabetes diagnosed, with a prevalence of diagnosed diabetes for the whole population at 6.2% (Public Health Agency of Canada (PHAC), 2009a). This may be underestimated as further research identified the prevalence rate for adults in Ontario to be at 8.8% in 2005 (Lipscombe & Hux, 2007). The Canadian Diabetes Association (CDA) estimates that 2.8 million Canadians currently live with diabetes and that number will increase to 3.7 million by 2020 (CDA, 2010).

After adjusting for age distributions between provinces and territories, the age-standardized prevalence of diagnosed diabetes was found to be higher in Newfoundland and Labrador, Nova Scotia, Manitoba, and New Brunswick. Prevalence was lower in the west; Alberta, British Columbia, and Saskatchewan. The prevalence for Ontario was higher than the national average; and for Quebec, the prevalence was lower than the national average (PHAC, 2009a).

The prevalence of diabetes is greater in high risk populations, including Aboriginal, Hispanic, Asian, South Asian and African communities. The age adjusted prevalence for Aboriginals in Canada is 2.5 to 5 times higher than that of the general population, with some individual communities having an age-adjusted prevalence as high as 26% (Dyck, Osgood, Lin, Gao & Stang, 2010). Additionally immigrants from high risk populations face increased risks for diabetes than that of the general population, as depicted in Figure 1. Immigrants from South Asia have an approximate four-fold increase in the risk of diabetes, those from Latin America and the Caribbean have a two-fold increase in the risk of diabetes, and individuals from sub-Saharan Africa also have a two-fold increase in the risk of diabetes (Creatore, Moineddin, Booth, Manuel, DesMeules, McDermott, et al., 2010).
Figure 1: Age-adjusted, sex-specific prevalence of diabetes (with 95% confidence intervals) in 2005 among recent immigrants to Ontario from the 15 countries of origin with the highest prevalence.

Furthermore, age, socioeconomic status, and obesity are associated with increased prevalence rates (Sanmartin & Gilmore, 2008; Statistics Canada, 2003; CDA, 2008). The incidence of diabetes rises steadily with age, as shown in Figure 2 (CDA, 2003; PHAC, 2009a; Statistics Canada, 2008).

Figure 2. Incidence percentages of diagnosed diabetes among people aged 1 year or older by age group and sex, in Canada between 2006-2007.

Adapted from Creatore et al. CMAJ 2010; 182:781-789.

Adapted from the PHAC’s National Diabetes Surveillance Survey, 2009.
Results from the Canadian Community Health Survey (CCHS) found that of those Canadians diagnosed with diabetes before the age of 50 years, 63% were South Asians, 57% were Aboriginal, 50% were Chinese, and 35% were self-described as White (Statistics Canada, 2003). Low socioeconomic status has also been associated with an increase in diabetes prevalence, with estimates at 2.8% among people in the highest income group compared to 3.9% in those in the lowest income group (Rabi, Edwards, Southern, Svenson, Sargious, Norton, et al., 2006). Finally, weight and obesity also increases the risk of diabetes, with the prevalence among underweight or normal weight individuals at 2.7%, 5.7% in those considered overweight, and 12.1% in those considered obese (Statistics Canada, 2003).

According to PHAC’s National Diabetes Surveillance System (NDSS), among adults aged 20 years and older, mortality rates of individuals with diabetes were twice as high, compared to individuals without diabetes (PHAC, 2009a). Diagnosed diabetes significantly shortened life expectancy for all ages. Women and men with diagnosed diabetes in the 25 to 39 year age groups had about an 8-year reduction in life expectancy (PHAC, 2009a). In 2005-2006, adults with diagnosed diabetes were hospitalized: a) three times more often with overall cardiovascular disease including, hypertensive disease (1,397,188), heart failure (49,665), heart attack (93,691), ischaemic heart disease (26,895), and stroke (23,912); b) seven times more often with chronic kidney disease (40,341); and c) 23 times more often with lower limb amputations, than adults without diabetes (3,001) (PHAC, 2009a). Moreover, as the diagnosis of diabetes is often delayed, 20-50% of people with type 2 diabetes present with microvascular and/or macrovascular complications at the time of diagnosis (Klein, Klein, Moss, et al., 1984; UK Prospective Diabetes Study (UKPDS) Group; 1998).

Etiology and natural history

The development of type 2 diabetes is attributed to beta cell dysfunction (insulin secretion and/or insulin deficiency), and insulin resistance. Pancreatic beta cells initially manage elevated glucose levels by secreting additional insulin. However, insulin secretion eventually fails, leading to impaired glucose tolerance, or prediabetes, and eventually clinical diabetes (Warren, Martin, Kroleswski, et al., 1990; Hamman, 1992). With the exception of rare forms of type 2 diabetes (e.g. maturity-onset diabetes of the young and diabetes-deafness syndrome) which account for < 1% of all cases of diabetes, most cases of diabetes are related to genes, the environment or both (Capes & Anand, 2001).

Type 2 diabetes is often diagnosed ‘by chance’, usually part of a routine physical examination or during treatment for other conditions. A US National Health Interview Survey found that only one half of the people with type 2 diabetes had symptoms at the time of their diagnosis (Harris, Flegal, Cowie, et al., 1998). The classic symptoms of diabetes include polydipsia, polyuria and polyphagia. However, other symptoms common with type 2 diabetes include fatigue, blurred vision, infection, recent weight loss, and/or neurologic symptoms in the feet.

The previous notion that type 2 diabetes was exclusively a result of poor lifestyle choices and not an inheritable metabolic disorder was proven otherwise with evidence from monozygotic twins, demonstrating a strong link in heritability, approximately 34-80%, particularly in certain ethnic groups and parents with diabetes (Rewers & Hamman, 1995). Type 2 diabetes is also
determined by a myriad of other lifestyle factors, including body mass index, waist circumference, diet and activity level (Knowler, Barrett-Connor, Fowler, et al., 2002; Orozco, Buchleitner, Gimenez-Perez, Roque i Figuls, Richter & Mauricio, 2008). Evidence for the environment as a determinant of diabetes is also apparent in studies of recent immigrants from a developing country to Canada. Research shows that immigrants to Canada of South Asian background have a 3-4 fold increase risk for diabetes than immigrants from Western Europe or North America (Creatore, et al., 2010; Lipscombe & Hux, 2007).

Consequences if left untreated

Short term consequences of type 2 diabetes if left untreated include diabetic ketoacidosis (DKA) and hyperosmolar nonketotic state (HNKS). Both acute consequences are rare in type 2 diabetes, but may occur with prolonged hyperglycemia, as a result of a concurrent illness or infection. DKA, typically a consequence in type 1 diabetes, may also be the first manifestation of type 2 diabetes, leading to a diagnosis. The mortality rate of DKA with appropriate management is < 3% (Capes & Anand, 2001). HNKS may occur with severe hyperglycemia, which leads to hyperosmolality and volume contraction. This life threatening acute complication typically presents in the elderly and despite treatment, has a mortality rate of up to 50% (Capes & Anand, 2001).

Long term consequences of type 2 diabetes are often described as microvascular (retinopathy, nephropathy, neuropathy) and macrovascular (cardiovascular disease) complications. Retinopathy, including proliferative retinopathy and macular edema is found in approximately 40% of the U.S. adult diabetes population (Kempen, O’Colmain, Leske, et al., 2004). Intensive glucose and blood pressure therapy has been proven to prevent the onset and progression of retinopathy (UK Prospective Diabetes Study Group, 1998). Nephropathy, including chronic kidney disease (CKD) and end-stage renal disease (ESRD) are common and potentially devastating complications of diabetes. It is estimated that 50% of people with diabetes have some form of chronic kidney disease (CIHI, 2001). The course of nephropathy is a step-wise progression, which begins as a subclinical disease, to the early developing of nephropathy, characterized by microalbuminuria (30-300 mg/24 hours), to eventually overt nephropathy (> 300 mg/24 hours) (Steele, 2001). To that end, epidemiological data suggests that 10-20% of individuals with diabetes develop ESRD (Ritz & Stefanski, 1996). Individuals with ESRD are among those at the highest risk for cardiovascular mortality, with a life expectancy of three years after diagnosis (Gerstein, Mann, Yi, et al., 2001).

Neuropathy is a likely complication that will develop in 40-50% of individuals within the first 10 years of the onset of diabetes, and is associated with sensory loss, pain and weakness (Dyck, Kratz, Karnes, et al., 1993). Among the various forms of neuropathy, polyneuropathy, damage to a diffuse set of peripheral nerves, particularly in the feet and legs, is the most common form (Bril & Perkins, 2008). Neuropathy may then lead to foot ulcers and infections, which may result in lower limb amputation. The onset and progression of neuropathy can be lessened with intensified glycemic control (Bril & Perkins, 2008).

It is estimated that 65-80% of people with diabetes will die of a cardiovascular event, of which a high proportion will occur without prior signs or symptoms of cardiovascular disease (CVD)
(Booth, Kapral, Fung, et al., 2006; Poirier, 2008). A meta analysis of over 698,000 individual data found that individuals with no history of diabetes, and a fasting glucose between 5.6 and 6.1 mmol/L and between 6.1 and 7.0 mmol/L had an increased risk of coronary heart disease by about 11% and 17% respectively (Emerging Risk Factors Collaboration, 2010). The NDSS estimates that Canadians with diabetes were three times more likely to be hospitalized for ischemic heart disease and myocardial infarctions, than Canadians without diabetes (PHAC, 2009a). The research evidence thus far demonstrates a modest reduction in CVD, specifically myocardial infarction with glucose intensification in people with type 2 diabetes. The modest effect with glucose intensification suggests a wider approach to diabetes management, targeting blood pressure and lipid management is also required (The ADVANCE Collaborative Group, 2008; The ACCORD Study Group, 2008; Gerstein, 2010).

Risk factors

The most important risk factors for type 2 diabetes are impaired glucose tolerance and/or impaired fasting glucose, or collectively known as prediabetes; in which case glucose levels are above normal targets, but not high enough to diagnosis as diabetes (Ur, Chiasson, Ransom & Rowe, 2008). Gestational diabetes or the delivery of a macrosomic infant (> 9 lbs) are additional risk factors for women. Hypertension, dyslipidemia, abdominal obesity and being overweight are modifiable risk factors for diabetes. Vascular disease, including coronary, cerebral and peripheral, are also risk factors for type 2 diabetes (Ur et al., 2008).

Non-modifiable risk factors include age (> 40 years of age), having a first-degree relative with type 2 diabetes, being a member of a high-risk population (e.g. people of Aboriginal, Hispanic, South Asian, Asian or African descent), or a diagnosis of schizophrenia are considered risk factors for type 2 diabetes. Finally, women with polycystic ovary syndrome are also considered high risk for diabetes (Ur, et al., 2008). A list of risk factors for type 2 diabetes is included in Appendix 1.

Rationale for screening

Diabetes is a disease that meets several disease screening principles: 1) diabetes represents an important health problem; 2) the natural history of diabetes is understood; 3) there is a recognizable asymptomatic period in which diabetes can be diagnosed; 4) tests are available that can detect the pre-symptomatic stage of diabetes; 5) screening is ongoing and not an isolated event; and 6) treatment after early detection yields greater benefits than in those with delayed treatment. (Engelgau, Narayan & Herman, 2000). Furthermore, prediabetes is predictive of type 2 diabetes in approximately 50-70% of cases (Canadian Agency for Drugs and Technologies in Health (CADTH), 2009). However, it is important to distinguish between screening and diagnosing. Screening involves attempts to detect asymptomatic disease and screening tests differentiate those at high risk from those at low risk. Screening methods may include simple, noninvasive/invasive and/or stepwise approaches (Calman, 1994; Morrison, 1992; Wilson & Jungner, 1968). In contrast, tests undertaken in individuals with symptoms presenting in a clinical setting are for diagnostic purposes and do not represent disease screening.
The American Diabetes Association (ADA) and the CDA recommend screening for type 2 diabetes in individuals ≥ 45 years and ≥ 40 years of age respectively, every three years, using a fasting plasma glucose test (Ur, et al., 2008; ADA, 2010). Adults at high risk for type 2 diabetes should be considered for screening at any age (ADA, 2010). Although the effectiveness of early identification of diabetes through mass screening compared with no screening has yet to be clearly shown, there is fair evidence to identify those at risk for future diabetes, identify, and if required, treat other CVD risk factors (ADA, 2010).

Screening strategies

Historically, screening for type 2 diabetes required fasting blood glucose (FBG) and/or an oral glucose tolerance test (OGTT), which uses both a fasting and a 2 hour post glucose load blood glucose value (Appendix 2). A growing body of literature demonstrates that glycated hemoglobin (A1C), OGTT and FBG are equivalent as predictors of retinopathy and nephropathy development, thus suggesting that A1C, OGTT and FBG may all be valid screening tools for diabetes (Bennett, Guo & Dharmage, 2007). The screening strategies considered in this review are FBG, OGTT, and A1C. The FBG test (defined as no caloric intake for at least eight hours) is also a component of diagnostic testing and is often preferred because it is faster to perform and more convenient for the patient. At a laboratory cost of approximately 6-10 dollars (Cdn), the FBG test yields a sensitivity of 40-60% with a specificity of 76% for identifying individuals with diabetes (Kahn, Alperin, Eddy, Borch-Johnson, Buse, Feigelman, et al., 2010; Engelgau, et al., 2000; Harris, 1993; CADTH, 2009). A FBG result of > of 7 mmol/L requires a second confirmatory glucose test on another day to diagnosis diabetes (Ur, et al., 2008).

The OGTT, considered to be the gold standard test for screening, uses both a fasting and 2-hour blood glucose level following a 75 gram glucose load. It is indicated when the FBG is not elevated enough to diagnose as diabetes (< 7 mmol/L), but yet above fasting blood glucose levels (≥ 5.6 mmol/L) (Ur, et al., 2008). The 2-hour blood glucose test in an OGTT provides a sensitivity of 97%, with a specificity of 100% (Harris, 1993). The cost of an OGTT is approximately 25-30 dollars (Cdn) (personal communication, Laboratory Services, Hamilton Health Sciences (HHS), September 15, 2009). If the FBG and 2-hour blood glucose levels are elevated (≥ 7 mmol/L and ≥ 11.1 mmol/L), then a diagnosis of diabetes can be made (Ur, et al., 2008).

The A1C test provides a retrospective average of glycemic control for the previous three months, by measuring the binding glucose to hemoglobin during the life span of red blood cells (Garlick et al., 1983). The A1C has a sensitivity ranging from 78-81% and a specificity of 79-84% (Bennett et al., 2007). It is relatively easy to collect, as the A1C test does not require fasting and has a laboratory cost of approximately 6-19 dollars (Cdn) (CADTH, 2009). The A1C test has traditionally been used to monitor long-term glycemic control, adjust therapy and assess risk for the development and progression of complications. In Canada, the A1C test is currently not recommended for screening type 2 diabetes (Ur, et al., 2008). However, the ADA recommends that the A1C test be used to screen for diabetes and/or assess the risk of future diabetes where appropriate, provided the A1C test is according to the National Glycohemoglobin Standardized Program (NGSP) and traceable to the Diabetes Control and Complications Trial (DCCT) reference assay. An A1C result of ≥ 6.5% would lead to a diagnosis of diabetes (ADA, 2010).
An additional type 2 diabetes screening tool that is currently being piloted is the CANRISK questionnaire; a 16 item survey designed to predict an individual’s ten year risk of developing type 2 diabetes (CADTH, 2009). The CANRISK is modeled on the validated Finnish questionnaire, (FINDRISC) and includes questions about family history, body weight, lifestyle and other factors (PHAC, 2009b). Participants aged 40-75 years are currently piloting this step wise screening approach which does not require laboratory testing, unless an individual is identified as high risk for type 2 diabetes. Currently the CANRISK method is detecting 5% new cases of undiagnosed diabetes and 15% new prediabetes cases, which would otherwise not be detected through FBG tests (PHAC, 2009b). However, the CANRISK questionnaire is currently being tested for validity across Canada.

The impact of diabetes screening needs to be put into context of costs; to the individual, as well as to the health care system. In Canada, a diagnosis of diabetes incurs individual financial costs ranging from 1,000 to 15,000 dollars annually, as a result of medication use, glucose monitoring, supplies, and complication prevention and management (CDA, 2010). Individuals also bear an emotional cost as a result of the diagnosis; one of anxiety and altered self-perception. Insurability is also an issue for individuals following a diagnosis of diabetes. Although there is limited research examining the adverse effects of screening for diabetes, a decrease in quality of life was not associated with screening (Edelman, Olsen, Dudley, Harris & Oddone, 2002). The health care costs of diabetes management are tremendous, as by 2020, it is estimated that diabetes will cost the Canadian healthcare system 16.9 billion dollars annually (CDA, 2010).

A recent review determined that the A1C test may be the most cost effective screening test for diabetes, as it is convenient and it also reflects post prandial glucose excursions (Waugh, Scotland, McNamee, Gillett, Brennan, Williams, et al., 2007). The OGTT was deemed too expensive and inconvenient, and the FBG test was incapable of detecting individuals with impaired glucose tolerance (Waugh, et al., 2007). The authors also conclude that screening for diabetes appears to be cost-effective for the 40-70-year age group, but even in the 40-49-year age group, the incremental cost-effectiveness ratio for screening versus no screening was 10,216 pounds or approximately 15,630 (Cdn) dollars per quality-adjusted life-year. However, the authors caution that the cost-effectiveness of screening for type 2 diabetes is determined as much by, if not more than, the degree of glycemic control and future treatment, than by assumptions related to the screening process (Waugh, et al., 2007).

**Interventions/treatments**

Individuals with a prediabetes diagnosis are strongly encouraged to undertake lifestyle modifications that include increasing physical activity, altering one’s diet and weight loss. It is estimated that a 5% reduction in initial body weight can reduce the risk of progression from prediabetes to type 2 diabetes by approximately 60% (Knowler et al., 2002). The initiation of pharmaceutical agents such as an alpha glucosidase inhibitor, biguanide or thiazolidinedione may also prevent the progress to type 2 diabetes by 30-60% respectively (Ur, et al., 2008).

The goals of treatment for type 2 diabetes are similar to prediabetes treatment, in that lifestyle modification is a cornerstone of management. Pharmacotherapy plays a more integral part in the
treatment of type 2 diabetes, with the initiation of oral medications if glucose targets are not obtained after 3 months of lifestyle management (Harper, Hanna, Woo, Dawson, Yale, MacCallum, et al., 2008). For individuals with marked hyperglycemia at the time of diagnosis, as evidenced by an A1C ≥ 9%, multiple oral agents may be considered, along with insulin (Harper, et al., 2008). The nature of type 2 diabetes is one that is progressive and dynamic and requires ongoing evaluation of management every three to six months. The goals of type 2 diabetes management are to ultimately achieve euglycemia or near normal glycemic targets, while minimizing adverse events (e.g. hypoglycemia), and preventing short and long term complications.

Current clinical practice.

In Canada, the CDA’s clinical practice guidelines recommends that all individuals should be evaluated annually for type 2 diabetes on the basis of demographic and clinical criteria (Grade D recommendation, consensus) (Ur, et al., 2008). However, screening for type 2 diabetes using a FBG test should be performed every three years in adults ≥ 40 years of age (Grade D recommendation, consensus). More frequent FBG testing or the use of an OGTT should be considered in high risk individuals (Grade D recommendation, consensus). Finally, testing with an OGTT should be considered in individuals with FBG levels suggestive of prediabetes (5.6-6.9 mmol/L) (Grade D recommendation, consensus) (Ur, et al., 2008).

A study using administrative health data examined diabetes screening patterns using laboratory tests (FBG, A1C and OGTT) in Ontario, Canada between 1995 and 2005. It was determined that in 2005, 37% of Ontario adults without diabetes were screened with a FBG test, 6.0% were screened using an A1C test and less than 1% of Ontarians underwent OGTT testing in any year between 1995–2005 (Wilson, Lipscombe, Rosella & Manuel, 2009). The authors conclude that despite the absence of the A1C test in the CDA’s diabetes screening recommendations, A1C testing among individuals without diabetes was increasing rapidly, and OGTT, which is recommended, was rarely performed (Wilson, et al., 2009).

2. Previous Reviews and CTFPHC Recommendations

In 1992, although the Expert Committee of the Canadian Diabetes Advisory Board (ECCDAB) did not provide recommendations for type 2 diabetes screening, they did recommend that adults with a FBG test of ≥ 7.8 mmol/L on at least two occasions should be diagnosed with diabetes (ECCDAB, 1992). In 1998, the clinical practice guidelines were updated and provided clear recommendations for the screening of type 2 diabetes, including testing for diabetes using a FBG every three years in adults ≥ 45 years of age. Those at high risk were recommended to be tested earlier and more often (Grade D recommendation, consensus) (Meltzer, Leiter, Daneman, Gerstein, Lau, Ludwig, et al., 1998). In 2003, the CDA’s clinical practice expert committee updated the guidelines to include screening for diabetes in adults ≥ 40 years of age, every three years with a FBG test (CDA, 2003).

In 2005, the CTFPHC published a guideline for the screening of type 2 diabetes mellitus to prevent vascular complications (Feig, et al., 2005). The following recommendations were made:
• There is fair evidence to recommend screening adults with hypertension for type 2 diabetes to reduce the incidence of cardiovascular (CV) events and mortality (Grade B recommendation).
• There is fair evidence to recommend screening adults with hyperlipidemia for type 2 diabetes to reduce the incidence of CV events and mortality (Grade B recommendation).
• There is good evidence to recommend treatment of overweight* individuals with impaired glucose tolerance (IGT) with lifestyle interventions to reduce the incidence of diabetes progression (Grade B recommendation).
• There is insufficient evidence to recommend treatment of overweight* individuals with IGT with metformin or acarbose to reduce the incidence of diabetes progression (Grade B recommendation).
• There is fair evidence to recommend treatment of overweight* individuals with IGT with acarbose to prevent cardiovascular outcomes and hypertension (Grade B recommendation).

*Body mass index (BMI, kg/m2) > 25 or > 22 in individuals of Asian descent

In 2003, the USPSTF made the following recommendations regarding screening for type 2 diabetes:
• The evidence is insufficient to recommend for or against routinely screening asymptomatic adults for type 2 diabetes, impaired glucose tolerance, or impaired fasting glucose (Grade I statement); and
• Screening for type 2 diabetes in adults with hypertension or hyperlipidemia is recommended. (Grade B recommendation) (Harris, Donahue, Rathore, Frame, Woolf & Lohr, 2003).

In 2008, the USPSTF group updated and revised the recommendations to the following:
• Screening for type 2 diabetes in asymptomatic adults with sustained blood pressure (either treated or untreated) greater than 135/80 mm Hg is recommended (Grade B recommendation).
• The current evidence is insufficient to assess the balance of benefits and harms of screening for type 2 diabetes in asymptomatic adults with blood pressure of 135/80 mm Hg or lower. (Grade I statement) (Norris, et al., 2008).

The absence of current Canadian guidelines, and the differences between the 2003 and 2008 USPSTF recommendations were the basis for selecting this topic for an update by the revitalized Canadian Task Force in 2010.
3. Analytic Framework

Figure 3: Analytic framework for screening for type 2 diabetes.

Abbreviation: Q: Question. (Adapted from Norris, et al., 2008).

4. Key Questions

1. What is the evidence for the clinical benefit of screening for type 2 diabetes using questionnaires, fasting blood glucose, oral glucose tolerance test, or A1C in asymptomatic adults 18 years of age or older at high risk or at average risk for diabetes complications to improve intermediate and final health outcomes?

2. What is the evidence for the harm of screening for type 2 diabetes using questionnaires, fasting blood glucose, oral glucose tolerance test, or A1C in asymptomatic adults 18 years of age or older at high risk or average risk for diabetes complications to improve health outcomes?

Contextual Questions:

1. What is the cost-effectiveness of screening asymptomatic adults 18 years or older for type 2 diabetes? Costs to the system and to patients will be included if found.

2. What are the patient values and preferences related to screening for type 2 diabetes?

3. What risk factors could guide screening for type 2 diabetes (e.g. age, hypertension, cholesterol, waist circumference, or ethnicity)?
4. What is the evidence that screening for diabetes in Aboriginal people, rural/remote, women and elderly improve health outcomes and/or mortality?
5. What are the clinical benefits and harms of early treatment (less than 12 months) of patients with type 2 diabetes compared with later treatment of patients for improvement of intermediate or final health outcomes?
6. What are the clinical benefits and harms of treatment of patients with impaired fasting glucose (IFG) and impaired glucose tolerance (IGT) compared with no treatment for improvement of intermediate or final health outcomes?
7. What process and outcome performance measures or indicators have been identified in the literature to measure and monitor the impact of screening for type 2 diabetes?
8. What are the clinical benefits and harms of treatment of patients with impaired fasting glucose (IFG) and impaired glucose tolerance (IGT) compared with no treatment for improvement of intermediate or final health outcomes?
9. What is the yield (accuracy, reliability, prevalence, and feasibility) of screening for type 2 diabetes with FBG, OGTT, and hemoglobin A1c in adult patients?

5. Literature Search and Review

USPSTF (Norris et al, 2008) searched MEDLINE®, and the Cochrane Library for relevant English language systematic reviews, randomized controlled trials and observational studies published between March 2001 and July 2007, related to the five questions regarding diabetes screening, diagnosis and potential adverse effects. Clinical Trials.gov was also searched for relevant trials. There were separate searches for adverse effects, adverse effects of treatment, hemoglobin A1C, screening and treatment. To answer key questions 1 and 2 the same search strategy will be implemented, and all searches will be updated to July 2010. To answer contextual questions 1 - 7, focused searches for systematic reviews and randomized control trials will be done of the same databases from 2005 to the present. For contextual questions 2-4, observational or epidemiological studies may be included, depending on the availability of data from systematic reviews and randomized controlled trials. The search for cost-effectiveness studies will include simulation modeling for cost-effectiveness and cost-benefit analysis.

6. Inclusion/Exclusion Criteria

The following inclusion criteria will be utilized (Norris, et al., 2008):

Methods:
English language, published randomized controlled trials, observational studies and systematic reviews for the effectiveness or adverse effects of screening and diagnosis of type 2 diabetes will be included.

Population:
Asymptomatic adults 18 years of age or older who are at high risk or average risk for type 2 diabetes complications (Appendix 1) will be included. Non-insulin dependent diabetes will be presumed to be type 2 diabetes. The USPSTF review included adults over the age of 20 years. The search will not be redone for studies including those between the ages of 18-20 years for
2001-July 2007; however, any new reports since July 2007 that studied people 18 years and over will be included.

**Interventions:**
Screening methods: Studies using the FBG, OGTT and A1C will be considered for this updated review. Screening questionnaires such as the CANRISK and FINRISK will be included in the search to determine if a two phase screening approach is effective.

**Comparators:**
The comparator for screening will be no screening or studies that compare the screening tests.

**Outcomes:**
The outcomes will focus on final health outcomes primarily: all cause mortality; cardiovascular mortality; stroke; myocardial infarction; end stage renal disease; angina; blindness; and severe retinopathy. For prediabetes, the intermediate outcome examined was incidence of type 2 diabetes, as this outcome was the primary outcome for the studies included. Outcomes will be prioritized by the Working Group using the GRADE process.

Harms of screening will also be collected. Harms will be prioritized by the Working Group using the GRADE process.

**7. Quality and strength of evidence criteria**

The retrieved included studies will be reviewed according to the criteria set out in the CTFPHC Procedure Manual, 2009), Appendices VII and VIII.
References

Appendix 1: Risk factors for Type 2 diabetes.

- Age ≥40 years
- First-degree relative with type 2 diabetes
- Member of high-risk population (e.g. people of Aboriginal, Hispanic, South Asian, Asian or African descent)
- History of impaired glucose tolerance or impaired fasting glucose*
- Presence of complications associated with diabetes
- Vascular disease (coronary, cerebrovascular or peripheral)*
- History of gestational diabetes mellitus
- History of delivery of a macrosomic infant
- Hypertension*
- Dyslipidemia*
- Overweight*
- Abdominal obesity*
- Polycystic ovary syndrome*
- Acanthosis nigricans*
- Schizophrenia

*Associated with insulin resistance

(Adapted from Ur, E., Chiasson, JL., Ransom, et al., 2008).

All laboratory values expressed as mmol/L. A result indicative of diabetes should be repeated to rule out laboratory error, unless the diagnostic criteria are supported by clinical symptoms. Adapted from the Canadian Diabetes Association’s recommendations and guidelines for the management of diabetes.
